

objects that it owns, then most of the cache contents may be primary. Conversely, if most requests are for contents it does not own, then its ratio of primary to secondary content may decrease. The contents of a hybrid cache may also change in accordance with the operational statuses of the other caches, caching criteria  
5 specified by an administrator, etc.

In an embodiment of the invention, when a cache must select one or more objects to remove in order to make room for a new object, it may consider its affinity for an older object (i.e., does it constitute primary or secondary content) and/or other criteria such as the object's age, popularity, validity, size, the cost of  
10 re-acquiring the object (e.g., from an origin server or other authoritative source), etc. These criteria, as well as others, such as how full the cache is, may also be used to determine whether to even cache the new object (e.g., when a request for it is received).

In another embodiment of the invention, a "warm-up" phase of operation  
15 is provided for a hybrid cache that is joining or re-joining (e.g., after recovery from a failure) a set of cooperative caches. During this phase of operation, the hybrid cache may retrieve requested data objects from another cache rather than from an origin server, thereby reducing the cost of populating the cache and preventing degradation of server performance.

In another embodiment of the invention, methods are provided for  
20 automatically distributing ownership of (or primary responsibility for) a failed cache among surviving caches. Similarly, a method is provided for returning a cache back into the group (e.g., through automatic reassignment of object ownership).

## DETAILED DESCRIPTION

The following description is presented to enable any person skilled in the art to make and use the invention, and is provided in the context of particular  
15       applications of the invention and their requirements. Various modifications to the disclosed embodiments will be readily apparent to those skilled in the art and the general principles defined herein may be applied to other embodiments and applications without departing from the scope of the present invention. Thus, the present invention is not intended to be limited to the embodiments shown, but is  
20       to be accorded the widest scope consistent with the principles and features disclosed herein.

The program environment in which a present embodiment of the invention is executed illustratively incorporates a general-purpose computer or a special purpose device such as a hand-held computer. Details of such devices (e.g.,  
25       processor, memory, data storage, display) may be omitted for the sake of clarity.

It should also be understood that the techniques of the present invention might be implemented using a variety of technologies. For example, the methods

described herein may be implemented in software executing on a computer system, or implemented in hardware utilizing either a combination of microprocessors or other specially designed application specific integrated circuits, programmable logic devices, or various combinations thereof. In particular, the methods described herein may be implemented by a series of computer-executable instructions residing on a suitable computer-readable medium. Suitable computer-readable media may include volatile (e.g., RAM) and/or non-volatile (e.g., ROM, disk) memory, carrier waves and transmission media (e.g., copper wire, coaxial cable, fiber optic media). Exemplary carrier waves may take the form of electrical, electromagnetic or optical signals conveying digital data streams along a local network or a publicly accessible network such as the Internet.

In one embodiment of the invention, a “hybrid” cache and methods of operating the hybrid cache are provided. In this embodiment, a hybrid cache is a cache having primary responsibility for serving one portion or share of a set of cacheable data (i.e., the cache’s primary content), as well as secondary responsibility for serving other cacheable data that is the primary responsibility of a different cache (i.e., secondary content). In other words, the set of data to be cached among multiple cooperating caches is partitioned among the caches so that for every data object in the set one of the caches has ownership or primary responsibility. Also, however, any of the data objects may also be stored in caches that do not own them. In one implementation of this embodiment a hybrid cache’s contents may be differentiated by those objects stored because of ownership (i.e., primary content) and those stored because of demand in the absence of ownership (i.e., secondary content).

The data objects cached in an embodiment of the invention may include audio, video, text and/or multimedia objects such as web pages or elements of

web pages. Origin servers that generate or maintain the objects may include database servers, web servers, application servers, and so on.

During cache operations in one embodiment of the invention, when a cache receives a request it will serve the requested object if it is currently stored.

5 If it is not currently stored, then, if the cache is the primary for the object, the requested object will be retrieved from an origin server, served and cached. Otherwise, if the cache is not the owner of the object the request will be passed to the primary cache (i.e., the cache having primary responsibility for the object). The primary cache will return the object to the cache, which will serve it and may  
10 also cache it.

At any particular time, a hybrid cache may have virtually any amount of primary content and secondary content. In an embodiment of the invention, the ratio of primary to secondary content may fluctuate automatically and dynamically during cache operations. Thus, rather than attempting to enforce or maintain a  
15 particular static ratio between partitioned data objects and replicated data objects in a cache, the ratio may fluctuate depending on the type of objects added and removed.

FIG. 1 demonstrates one computing environment in which a hybrid cache may be implemented, according to one embodiment of the invention. The  
20 environment of FIG. 1 includes four hybrid caches or cache servers 102, 104, 106 and 108. Some or all of the caches may participate in a cache cluster – a loosely coupled collection of cooperating cache instances. The caches are coupled to origin servers 110, 112, which generate data objects for clients, users and other requestors. The caches are coupled to clients 130, 132 via network 120, which  
25 may comprise the Internet. A cache may also be linked directly to a client, or may be linked via some path other than network 120, such as client 134. In alternative embodiments of the invention, any number of hybrid caches or cache servers may

cooperate (e.g., two or more), and may be coupled to any number (i.e., one or more) of origin servers. Further, in one particular alternative embodiment, another layer of hybrid caches or cache servers (i.e., one or more) may be interposed between caches 102-108 and the origin servers or between caches 102-108 and the clients. In addition, although FIG. 1 depicts each cache as operating on a separate machine, multiple hybrid caches may operate on a single machine in another embodiment of the invention. Yet further, a hybrid cache may be operated on an origin server.

In the illustrated embodiment, caches 102-108 store data objects such as web pages, portions of web pages, images, data from a database and other items to be served to clients operating suitable applications (e.g., a web browser, a database application). Clients 130-132 may operate different applications and/or different operating systems. Illustratively, however, data stored on or generated by origin servers 110, 112 define a domain of cacheable data that may be requested by the clients.

In FIG. 1, the domain of cacheable data is partitioned among the four hybrid caches so that each is the “owner,” or assumes primary responsibility for, approximately one-fourth of the domain. Any suitable method of dividing the domain among the caches may be applied. For example, the name of a data object may be hashed via a hashing function to produce a hash value. Each hybrid cache may then assume primary responsibility for objects that hash into its quarter of the possible hash values. Or, the modulo of the hash value over the number of caches may be calculated, with each cache taking ownership of objects that hash to it.

In one embodiment of the invention, a data object’s “name” may comprise or be generated from one or more components (e.g., a file name, object name or other identifier of the object). For example, a unique object identity may be derived from an identifier (e.g., URL) of the object, one or more session attributes

(e.g., of a requestor's session), information or parameters included in a request for the object, etc.

In an embodiment of the invention in which all caches are not of equal capacity or performance capability, weights may be assigned or the method of allocating ownership may be altered to take the difference(s) into account. Thus, if one cache has twice the storage capacity of another, it may receive ownership of twice as much content as the other.

Each cache can therefore easily determine not only whether it is the primary cache for a given object but, if it is not, it can determine which of the caches is the primary. A cache may be required to always store the data objects that it owns. Alternatively, a cache may be able to remove primary content (content it owns) from storage under certain circumstances (e.g., it is rarely requested, it is very large, it quickly becomes invalid, it can be retrieved from an origin server or other source quickly and inexpensively, other content is requested more often).

In addition to the partitioned data that a hybrid cache may store, all or a subset of the domain of cacheable objects may be stored (or replicated) at one or more hybrid caches other than their primary cache. Thus, each data object will have one primary cache, but may also be stored in any another cache if it meets the specified criteria, if any. In one embodiment of the invention only the most popular objects (i.e., those requested most frequently) are, or may be, stored as secondary content. In other embodiments, however, other criteria may be considered, such as size, validity, cost, etc. Thus, smaller objects, highly valid objects and objects that are expensive to retrieve or replace may be prime candidates for storage as secondary content.

For example, in one embodiment of the invention, if the caches are web caches configured to store web pages and/or parts of web pages, a home web page

may be a particularly popular page accessed by many users. That page may therefore be stored in most or all of the caches. Or, the X (e.g., 100, 1000) most requested objects may be identified (e.g., from a log file) and identified as being replicable across the caches.

5 In another embodiment of the invention, a cache may store or attempt to store all objects that are requested of it. When the cache is full, or nearly full, and space must be made (e.g., through garbage collection), then various criteria discussed herein (e.g., ownership, demand, validity, size, cost) may be considered in deciding which objects may remain in the cache and which should be removed.

10 In a present embodiment of the invention, the set or subset of data objects that may be stored as second content is dynamic and may be defined by any suitable criteria. In particular, the replicable objects in this embodiment may comprise the most popular 10% of the cacheable data objects, the 100 objects that are requested most frequently, etc. Over time, the members of this set will  
15 change. Alternatively, however, these data objects may be defined statically.

Because more than one cache may store a particular object, if that object is invalidated (e.g., by an origin server), an invalidation message may be broadcast to each cache (or each cache that contains the object) – by the origin server, the primary cache for the object, or some other entity.

20 Thus, in a present embodiment of the invention, the combination of ownership-based caching (e.g., primary content) and demand-based caching (e.g., secondary content) allows the system to cache a large number of data objects. As a result, cache misses and the need for (and cost of) updating cached data may be decreased, but popular data will be available from more than just one of the  
25 caches, thereby increasing cache performance and decreasing response time.

During operation of the system depicted in FIG. 1, caches 102-108 receive data requests and serve the requested data, either from their cache storage or after

retrieving the data from an origin server or another cache. Therefore, a user or data requestor may be guaranteed that a requested data object will be served, regardless of which cache receives the request. Advantageously, if the request is received at a cache other than the primary cache of the requested object, that cache  
5 may retrieve the object directly from an origin server (i.e., without routing or passing the request to the object's primary cache). In other embodiments, however, the request may be forwarded to the primary cache if received at a secondary.

The size of the caches (e.g., the total cache space) and the size of the  
10 domain of cacheable data may help determine how much data may be stored as secondary content or replicated across multiple caches. For example, if each of the caches in FIG. 1 is approximately 1GB in size, and the domain of cacheable data is almost 4GB, then there may be little space available in a cache for storing anything but primary content, thereby limiting the number (and/or size) of data  
15 objects that may be cached as secondary content. But, if the domain of cacheable data is much less, then the system may be able to replicate or store as secondary content almost all the data objects.

However, in typical computing environments, the ratio of primary content to secondary content to be stored in a hybrid cache will be much less obvious or  
20 less readily discernable. In particular, the total amount or size of cacheable data is often not known or easily ascertainable. As described below, an embodiment of the invention is well suited for such environments because the ratio of primary to secondary content is able to fluctuate in response to the data requests. Alternatively, a static ratio of primary to secondary content may be attempted or  
25 used as a baseline for deciding which data objects to cache.

In one embodiment of the invention, a hybrid cache may be initially operated with all or most of its space allocated to storing only partitioned data that

it owns (e.g., primary content) or, conversely, data owned by other caches (e.g., secondary content). Then, over time, as decisions are made to cache new objects and/or to remove objects to make room for new objects, it may be determined that many requests are received for the other type of data, and therefore more and more  
5 of that type of data will be cached.

In this embodiment, the ratio of primary to secondary content that a hybrid cache contains will fluctuate automatically and dynamically, based on the objects chosen to be cached and the objects removed to make room for new objects when the cache is full. More particularly, the garbage collection or other process used  
10 to clear up cache space for new objects may apply specified selection factors or criteria to determine which objects to remove. Thus, over time, the garbage collection process may be used to favor the retention of certain types of data over other types.

In an embodiment of the invention, the criteria used to clear out older  
15 objects to make room for newer objects may include any of the following (and others not specifically enumerated here): popularity, validity or size of an object, the cost of recovering the object (e.g., retrieving it from an origin server), whether the object constitutes primary or secondary content, etc. Further, the age (i.e., length of time in the cache) of an object may be considered, possibly in  
20 conjunction with other factors such as popularity or validity. Thus, an object's popularity and/or validity may be considered at a certain age of the object, or over time.

In general, in one embodiment of the invention a cached object is more likely to be removed from the cache (e.g., to make room for a new object) if its  
25 popularity and validity are low, the cost of repopulating the object is low, it is relatively large in size and it is secondary rather than primary content.

Illustratively, the cost of repopulating an object may be provided by an origin server when the object is provided to the cache by the server.

Very popular objects may often constitute secondary content for a cache, but if the popularity factor is given sufficient weight, then the most popular  
5 objects will remain in the cache even though they are secondary. In this embodiment, then, the ratio of primary to secondary content stored in a cache will be dynamic, and depend on the objects' popularity, validity, and/or other selected criteria.

A system administrator may adjust the criteria in whatever manner is  
10 desired. The various criteria may be assigned different weights depending upon the administrator's preferred caching policy. Other criteria not specifically mentioned above may also be used to enable the cache to dynamically adjust its contents and the ratio of primary to secondary content.

Because the garbage collection process may be used to apply a selected  
15 caching policy, the decision of whether to cache a particular object may be made more superficially. For example, if the ratio of primary to secondary content at a particular time is relatively high, then when the cache is determining whether to cache a newly requested object, the decision may turn on whether the new object is primary or secondary. Illustratively, because the cache has little secondary  
20 content at the time, such content has not been requested very often and so the cache may apply a bias against it.

However, in other embodiments of the invention a decision whether to cache an object may be based on several criteria or factors. In one embodiment, the same criteria that are used during garbage collection may be used to determine  
25 whether to cache a new object. In addition, other factors may be considered, such as the total cache utilization at the time, the cost of redirecting a request for an object to another cache, etc. For example, if a large amount of cache space is

currently unused, then even if other factors weigh against storing a particular object it may be cached anyway. Illustratively, if it turns out that the object is of little value, the garbage collection process may quickly remove the object when the cache is full or nearly full.

5           FIG. 2 demonstrates one method of operating a hybrid cache (e.g., as part of a cluster) according to one embodiment of the invention.

          In state 202, a request for a data object is received at a first hybrid cache in a set of multiple caches. The data that is cached in this embodiment of the invention may include web pages, portions of web pages, and so on, and may  
10       comprise any type of data (e.g., text, audio, images).

          In state 204, the first cache determines whether it presently stores the requested object, or, more particularly, a valid version of the object. If so, in state 206 the first cache serves the object and the method ends.

          In state 208, the first cache does not currently store the requested object  
15       and therefore determines which of the multiple caches is the primary cache for, or owner of, the object. Illustratively, this determination requires hashing a name or identifier of the object. If the first cache is the object's primary cache, then the illustrated method advances to state 212.

          Otherwise, in state 210 the first cache determines whether the object's  
20       primary cache is alive or on-line. If so, the method continues at state 218; otherwise it proceeds to state 212.

          In state 212, the requested data object is retrieved from an origin server (e.g., web server, application server) and, in state 214, is served to the requestor.

          Then, in state 216, the object is cached in the first cache if it meets the  
25       operative criteria. For example, the cache may be configured to always cache primary content; therefore, if the first cache is the primary cache for the object, the object will be cached. If the first cache is not the primary cache for the object,

then the object may only be cached if it meets the criteria, if any, for caching as secondary content. In different embodiments of the invention, different criteria may be applied. Illustratively, all objects may be considered cacheable as secondary content (e.g., if there is space available).

5           In state 218, the primary cache, which is not the first cache, is alive, and so the first cache determines in this embodiment whether to retrieve the requested object from the primary or to just pass the request to it. If the object is retrieved, then the first cache has the opportunity of caching it. However, depending on factors such as the size of the object, cost of retrieving it, and so on, the applicable  
10       caching policy may indicate that the primary cache should handle the request. In the illustrated method, if the requested object is, or may be, suitable for caching as secondary content, then the illustrated method proceeds to state 220 to retrieve the object. Otherwise, it advances to state 222. If the determination of state 218 cannot be made, then the method may proceed directly to state 222, 220 or 212 in  
15       different embodiments of the invention.

          In state 220, the requested object is retrieved from the primary cache and the method returns to state 214 to serve the object and possibly cache it.

          In state 222, the first cache routes or forwards the request to the object's primary cache, which will serve the object (after retrieving it, if necessary, from  
20       an origin server). Along with the data request (e.g., in HTTP), the first cache may send along any information that it extracted from or developed regarding the request (e.g., name or identifier of the requested object, verification that the request is for a cacheable object). The illustrated method then ends.

          In one alternative embodiment of the invention, when a cache receives a  
25       request for a data object that it does not own, it will always forward the request to the primary cache of the object (i.e., rather than just retrieving the object). The primary cache will then retrieve the object and return it to the cache that received

the request. That cache will serve the data object to the requestor and decide whether to cache it.

When one hybrid cache in a cluster or set of cooperating caches fails, “ownership” of its primary content is automatically distributed among the surviving caches. Illustratively, rather than taking the full spectrum of content (i.e., the full domain of cacheable data) and re-partitioning it, just the primary content of the failed cache may be partitioned. This may facilitate faster recovery when the cache (or a replacement) is brought back on-line. Any suitable method of allocating the failed cache’s content among the survivors may be applied, such as an additional hashing function, dividing the hash values assigned to the failed cache, etc. Thus, at any given time, each cache merely needs to know which of its neighbors or cooperating caches are alive in order to identify the owner of a particular data object.

Some content that had been secondary for a surviving cache may now become primary after a cooperating hybrid cache fails, thereby altering the manner in which garbage collection and/or caching decisions are made. Over time, the other caches will likely store more and more of the failed node’s primary content.

When a failed cache recovers or re-joins the cache cluster, it will re-assume ownership of its primary content. However, in one embodiment of the invention, a “warm-up” phase is applied during the cache’s recovery. In this phase, the recovering cache receives content digests from each of the other cooperating caches. Then, when the recovering cache receives a request for an object (especially primary content) that it does not currently cache, it may pass the request to, or retrieve the requested object from, one of the other caches that stores the object. The cost of retrieving the object from another cache will likely be less than retrieving it from an origin server.

The content digest(s) generated for or used by the recovering node need not be complete or thorough. A content digest may be generated to include most of the objects for which the recovering node is re-assuming ownership, the most popular objects, the data objects served in the last thirty minutes, etc.

5       The warm-up phase may last for a period of time (e.g., twenty minutes), a number of data requests (e.g., one hundred), etc. In one embodiment, the warm-up phase may last until the success rate of retrieving or serving the requested object from a neighboring cache falls below a threshold. In another embodiment, the warm-up phase runs until the average or expected cost of satisfying a request  
10       through another cache is no longer cheaper than sending a request directly to an origin server.

      If, for example, the cost of retrieving an object from an origin server is 10, then until the average cost of retrieving objects from the other caches reaches or  
15       nears 10, the warm-up phase may continue. The average cost of relying on the other caches may be determined by multiplying the percentage of requests sent to other caches that are satisfied by those caches by the cost of doing so (e.g., the  
      “short-cut” cost) and multiplying the percentage of requests sent to the other  
20       caches that fail by the sum of the short-cut cost and the cost of going to an origin server afterward, and then adding the products. Thus, if the cost of satisfying a request from another cache is 2 and at some point the other caches are providing,  
      on average, 40% of the requested data objects, then the average cost of satisfying a request at this point of the warm-up phase is  $(.40 * 2) + (.60 * (2 + 10)) = 0.8 + 7.2 = 8.0$ . Thus, the warm-up phase may be continue in this example because the  
25       average cost is still significantly less than the cost of retrieving objects directly from the origin server. Other factors may also be considered when determining whether and when to end a warm-up phase, such as the number and size of other

caches, the type of traffic received at the recovering node (e.g., primary vs. secondary), how full the recovering cache is, etc.

In one embodiment of the invention, a cache may be configured to save or remember previous configurations (e.g., when all caches are operating, when one  
5 or more caches have failed). Then, when the configuration of the cooperating caches changes (e.g., one cache fails or comes back online), the cache can quickly revert to the saved configuration.

FIG. 3 demonstrates one method of operating a hybrid cache during a warm-up phase, according to one embodiment of the invention. In this  
10 embodiment, the warm-up phase may initiate a new cache's entry into the cluster or mark the return of a cache after its recovery from a failure.

In state 302, the cache receives one or more content digests, or similar information, from the other members of the set or cluster of hybrid caches. As described above, the content digests may identify to this cache some or all of the  
15 data objects currently stored at the other caches.

In state 304, a request is received at the cache for a data object that is not yet stored in the cache.

In state 306 the cache attempts to determine whether another cache in the cluster or set of cooperating caches may store the object. In the illustrated  
20 method, this determination is made with the aid of the content digests received in state 302. If the content digests indicate that another cache may store the object, the method advances to state 310; otherwise it continues at state 308.

In state 308 the requested object is retrieved from an origin server because, though it may be cheaper to get the object from another cache, the content digests  
25 (or other information provided by the other caches) indicate that none of them has the object. After state 308, the illustrated method advances to state 312.

In state 310, the requested data object is retrieved from another cache that reported in its content digest that it stored the object.

In state 312, the object is served to the requestor.

In state 314 the cache determines whether the object constitutes primary  
 5 content or secondary content (e.g., based on a hash value computed from an identifier of the object). If the object is primary content, it is cached in state 316 and the method ends.

Otherwise, in state 318 the object is cached if it satisfies specified criteria. If, for example, the object is so popular that it may or should be stored as  
 10 secondary content, then it will be cached.

In an alternative embodiment of the invention, the hybrid cache may decide earlier (e.g., when the request is received) if the requested data object constitutes primary or second content, and then take appropriate action. In another alternative embodiment, the hybrid cache may not automatically store all  
 15 primary content. Instead, it may apply the same, or similar, criteria to determine whether to cache an object, regardless of whether it is primary or secondary content.

In a hierarchical or layered system of cooperating hybrid caches, such as a system comprising multiple cache clusters, requests may be received at a first  
 20 cluster and be passed through to a second cluster only if the first cannot satisfy them. The second cluster may be followed by another cluster or a set of origin servers. In such a system, an embodiment of the invention may be applied in which each cluster functions as described above. In particular, each cluster may view all entities behind it (e.g., other clusters and/or origin servers) as a unitary or  
 25 collective data source, just as the caches in a single cluster system view their origin servers or as a client views the cache cluster. In another embodiment of the invention, however, the concept of tertiary content may be introduced. In this

embodiment, the ratio of primary to secondary to tertiary content may automatically and dynamically fluctuate as described above for primary and secondary content.

In another hierarchical cache model, a single cluster or set of caches may include disk storage in addition to solid-state memory. In this model, data objects removed from a hybrid cache's memory during garbage collection may be stored on a local disk (or similar device) instead of being discarded. In different embodiments, only large objects may be stored on a cache's disk, only primary content, only objects that remain valid for relatively long periods of time, etc. Virtually any criteria, such as those described above, may be applied to determine whether to move an object to disk. An object stored on disk may be able to migrate back to cache memory (e.g., if its popularity increases).

FIG. 4 is a block diagram depicting a hybrid cache according to one embodiment of the invention. In this embodiment, hybrid cache 400 comprises a cache engine 402, monitor 404 and administrator 406.

Cache engine 402 receives and responds to data requests (e.g., HTTP requests from users), receives data objects from origin servers and from cache engines of other caches, performs garbage collection on the cache contents when necessary, decides whether to cache a new object, maintains statistics, generates content digests, etc. Cache engine 402 includes cache space (e.g., memory) of virtually any size.

Monitor 404 monitors the operational status of hybrid cache 400. For example, monitor 404 may be configured to periodically ping or query the cache engine to determine if it is operational. If not, monitor 404 may initiate a recovery process. The monitor may also be configured to determine the operational status of other caches, facilitate the addition of a new or recovering cache into a group of cooperative caches (e.g., a cluster) that includes cache 400, etc.

Administrator 406 facilitates system management functions for cache 400. For example, the administrator may provide an interface or routines to allow a system manager to reconfigure the cache, access cache statistics, start or stop operation of the cache, etc.

5 In a clustered or other cooperative environment, cache engine 402 may be coupled to an engine of another cache (e.g., to receive a data object or content digest), and monitor 404 may be coupled to another monitor to track its operational status. In a cooperative environment, one cache (e.g., one monitor, one administrator) may be deemed the master for purposes of coordinating the  
10 addition of a new cache, distribution of a failed cache's ownership of data objects, etc.

Hybrid cache 400 may operate according to a dynamic set of parameters or criteria, which may be the same for each cooperating cache. The parameters may be maintained or dynamically modified through administrator 406. Each cache  
15 may or may not have identical storage capacity. In one embodiment of the invention the percentage of all cacheable data that will be owned by a given cache may be determined as follows:

*ownership percentage = (cache capacity / total of all caches' capacities) \* 100*  
and the actual amount of data would be this percentage of the total size of the  
20 cacheable data. In another embodiment, the cacheable data is partitioned among multiple caches on the basis of some logical grouping. For example, if different data objects are served for different applications, the data may be partitioned by application. Or, objects having similar characteristics (e.g., of the same language, belonging to a particular department or organization, images, text objects) may be  
25 kept together.

The foregoing descriptions of embodiments of the invention have been presented for purposes of illustration and description only. They are not intended to be exhaustive or to limit the invention to the forms disclosed. Accordingly, the above disclosure is not intended to limit the invention; the scope of the invention  
5 is defined by the appended claims.
